Abstract

We study the association between the stock liquidity of SMEs in the US and their likelihood of bankruptcy, using a dataset that comprises information on 5,075 firms over the time period from 1984 to 2013 using the hazard model of Campbell et al. (2008). We find that less liquid stocks are associated with higher probability of bankruptcy, although there is substantial heterogeneity across

industries regarding the predictive power of the liquidity measure on the likelihood of bankruptcy. Furthermore, the exchange where the SMEs are listed also affects the likelihood of bankruptcy. Classification performance tests conclude that adding a liquidity measure variable to the Campbell (2008) model improves its predictive power.

JEL classification: G12, G14.

Keywords: Market Liquidity; Liquidity Measures; Bankruptcy; Hazard Model.

1. Introduction

Stock liquidity is an important variable in financial markets. The main contribution of this paper is to investigate the extent to which stock liquidity affects the likelihood of bankruptcy of SMEs and thus whether liquidity measures can improve the effectiveness of the hazard model of Campbell et al. (2008).

More liquid stocks are usually associated with lower transaction costs and liquidity risk premiums (see, e.g., Becker-Blease and Paul (2006), and less liquid stocks are usually associated with lower credit ratings and a higher risk of default (see, e.g., Odders-White and Ready (2006). There are several stock liquidity measures available in the microstructure literature, such as the trading volume, share turnover, bid-ask spread, Amihud (2002) and Florackis et al. (2011) liquidity (or illiquidity) ratios. Each of these liquidity ratios captures different aspects of stocks (Chai et al., 2010).

A very simple stock liquidity measure is, for instance, trading volume. Nevertheless, it does not take into account some important stock liquidity related characteristics, for instance, price and return, and the bid-ask spread and the speed at which stock trading occurs. Consequently, other more sophisticated liquidity measures were developed, for instance, the Gabrielsen et al. (2011) liquidity ratio, which considers the trading volume and the market capitalization, and the Amihud (2002) and

Florackis et al (2011) illiquidity ratios, which consider trade volume, stock return and the turnover ratio.¹

In this paper we use the following stock liquidity (or illiquidity) measures: Atkins and Dyl (1997) (i.e., the zero-return measure), and Lesmond et al. (1999) (i.e., the turnover ratio), and the Amihud (2002) and Florackis et al. (2011) illiquidity ratios. We examine the relationship between stock liquidity and firm value and the probability of bankruptcy of US SMEs, using a data sample that comprises information on 5,075 US SMEs firms, over the time period between 1984 and 2013.

Extant literature suggests that higher stock liquidity is positively associated with firm value and performance and encourages the use of more efficient managerial compensation schemes (Holmström and Tirole, 1993). There are also studies suggesting that higher stock liquidity reduces managerial opportunism and direct issuing costs, and improves corporate governance (see, e.g., Maug, 1998; Edmans, 2009; Butler and Wan (2010) and Butler et al. (2005).

Studies on SMEs cover a wide range of research areas, for instance, the determinants of the SMEs' profitability and capital structure (e.g., Kolari and Shin, 2004; and Sogorb-Mira, 2005) and the SMEs' loan structure (e.g., Berger and Udell, 2004).

There are several bankruptcy prediction models available in the literature, for instance, the Altman (1968) model, based on accounting information, the Vassalou and Xing (2004) model, based on contingent claims analysis, and the Shumway (2001) and Campbell et al. (2008) models, based on a survival analysis that considers both accounting and market information. In this paper we examine the relationship between stock liquidity, measured by the four liquidity measures described above and the probability of bankruptcy, using the Campbell et al. (2008) hazard model and a dataset that comprises information on 4,656 healthy SMEs and 419 bankrupt SMEs listed in the US market.

Our results show that all the above liquidity measures are negatively associated with the probability of bankruptcy, i.e., the higher the stock liquidity the less likely is the bankruptcy probability. We check the robustness of our results by using the predictive ability test and examining the area under the receiver operating characteristics curve, and both confirm that the use of a stock liquidity measure variable in the baseline Campbell et al. (2008) model improves the predicting power of the discrete-time duration-dependent hazard model. Additionally, the average stock liquidity of the bankruptcies sample (419 firms) is lower than the average stock liquidity of the non-bankruptcies sample (47,233 firms). More specifically, the turnover and Amihud (2002) liquidity ratios of the bankruptcies sample

¹ Chai, D., Faff, R. & Gharghori, P. (2010), "New evidence on the relation between stock liquidity and measures of trading activity." *International Review of Financial Analysis*, Vol. 19, No.3: pp. 181-192., classify the liquidity measures into four categories: trading cost, price impact/depth, resilience and trading speed/frequency. Goyenko, R. Y., Holden, C. W. & Trzcinka, C. A. (2009), "Do liquidity measures measure liquidity?" *Journal of Financial Economics*, Vol. 92, No.2: pp. 153-181. classify the liquidity measures into two categories: low-frequency spread proxies and low-frequency price impact proxies.

are approximately 2.5 times higher than those of the non-bankruptcies sample. The Florackis (2011) liquidity ratio of the bankruptcies sample is roughly twice that of the non-bankruptcies sample, and the Zero-Return ratio of the bankruptcy sample is 1.5 times higher than that of the non-bankruptcy sample.

The remainder of the paper is organised as follows. Section 2 discusses the methodology. Section 3 describes the data sources and variables. Section 4 presents the results. Section 5 concludes.

2. Methodology

2.1. Discrete-Time Duration-Dependent Hazard Model

We use a discrete-time duration-dependent hazard method, used by Bauer and Agarwal (2014) and El Kalak and Hudson (2016), to examine the effect of stock liquidity on the probability of failure of SMEs by following the model developed by Campbell et al. (2008). Bauer and Agarwal (2014) compare the accuracy of several bankruptcy prediction models and conclude that the hazard models are more accurate than the z-score and contingent claims models, with their results still being valid when the economic value of each model is considered. Hwang (2012) shows that there are advantages in using a discrete-time duration-dependent hazard rate, since it allows, for instance, the coefficients of the firm-specific predictors to be dynamic over time. Nam et al. (2008) contend that the application of discrete-time duration-dependent hazard model can be comparable to the application of a panel logistic model incorporating a macro-dependent baseline hazard.

The firm i 's conditional probability of default in the time interval t , given it survives up to this time is given by the discrete time hazard function (λ):

$$\lambda(t|X_{i,t}) = Pr(T = t|T \geq t, X_{i,t}) \quad (1)$$

where T is a discrete time failure, $T = t$ means a failure within the time interval t , and $X_{i,t}$ is the value of covariates of firm i up to the time interval t .

The hazard model is defined as follows:

$$h(t|X_{i,t}) = h(t|0) \cdot \exp\{X_{i,t}'\beta\} \quad (2)$$

where $h(t|X_{i,t})$ is the individual hazard rate of firm i at time t .

The discrete hazard model suits fairly with the features of our empirical data because it is coherent with the binary nature of our model dependent variables and the time-series, and the cross-sectional nature of the dataset. In line with previous literature, we estimate our hazard models using a discrete-time framework with random effects, controlling for unobserved heterogeneity and shared frailty, given by Equation (3).

$$P_{i,t} = \frac{e^{\alpha(t) + \beta X_{i,t}}}{1 + e^{\alpha(t) + \beta X_{i,t}}} \quad (3)$$

where $\alpha(t)$ is the time-varying covariate which captures the baseline hazard rate, β is the coefficient value of the covariate x , and $P_{i,t}$ represents the probability that the bankruptcy of firm i occurs at time t .

2.2. Hazard Rate Specification

If all the covariates are equal to zero, there are numerous techniques to proxy the baseline hazard function, $\alpha(t)$, for instance, using the $\log(t')$, where t' is the survival period, a polynomial in survival time, a fully non-parametric, or the piece-wise constant (Jenkins, 2005). In order to choose the most appropriate method, we have to estimate and analyse first the survival and the hazard curves.

Figure 1A shows that the survival probability as a function of the firms' age, estimated using the Kaplan-Meier estimator, and our sample average survival probability decreases to around 0.85 as firms' age increases reaching twenty years, being henceforth more or less constant. We estimate the hazard model curve to decide about the appropriate method to be used to determine the baseline hazard.

Figure 1B shows the hazard rate curve as a function of the firms' age, where we can see that the hazard rates differ significantly according to the age groups. Therefore, we use a fully non-parametric baseline hazard model with age dummy variables to define the baseline hazard rate (Jenkins, 2005). The number of age-specific dummies is equal to the maximum survival time of the dataset (i.e., 29 years), nevertheless, we generate 28 age-dummies to avoid perfect multicollinearity that can arise from the dummy variable trap.

[Insert Figure 1 here]

2.3. Robustness Tests

2.3.1. Predictive Ability Test

To test the models predictive ability, we carry out a bankruptcy out-of-sample prediction test, parallel to that used by Shumway (2001), on the period (2009-2013), and re-calculate our estimations made on data for the time period between 1984 and 2008. Subsequently, we rank firms into deciles, year by year, according to the bankruptcy probabilities, where firms that are more probable to default in the next year are in the first decile. Then we determine for each decile the percentage of firms that have defaulted. The model with the best performance is the one that has a higher percentage of defaults in the top deciles.

2.3.2. Receiver Operating Characteristics Curve

The receiver operating characteristics curve (ROC) is a widely used measure for evaluating the accuracy of the predictive power of a model. ROC curves identify the true positive rate against the false positive rate as the threshold to discriminate changes between solvent and insolvent firms. The area under the ROC curve (AUROC) indicates the accuracy of the predictive power of the model, where “1” means a perfect model (Anderson, 2007).

3. Data Sample and Regression Variables

3.1. Data Sample

Our dataset comprises information on SMEs bankruptcies for the US market over the time period between 1984 and 2013. We define an SMEs firm as a firm with no more than 500 employees and an average yearly turnover below \$7.5 million.² We use two main sources for the data collection: the Compustat security database, for stock prices, trading volumes and shares outstanding, and the Compustat-Fundamentals Annual database, for accounting information.

In line with previous studies, we exclude the SMEs operating in the financial, insurance and utility sectors. The SMEs operating in the financial, insurance that were eliminated from our sample have industrial classification (SIC) codes that range between 6,000 and 6,999. The SMEs operating in regulated utility markets have industry codes are between 4,900 and 4,949. We also removed from our sample non-US firms and observations with missing data regarding the control variables or dependent variables. Our final data sample comprises information on 4,656 healthy firms and 419 bankrupt firms and our panel data has 47,652 observations.

To eliminate the possibility of any wrong entries in our sample, we only consider observations with positive values for the common equity, total assets, stock price at the end of the fiscal year and number of shares outstanding. We control for the industry effect by categorising the SMEs into nine distinctive industry categories, and extreme outliers were eliminated. We winsorised our independent variables between the 5th and the 95th percentiles and lagged the covariates by one-time period to ensure that the information used was available at the beginning of the time periods.

Table 2 shows the distribution of our data sample over time sample time period.

[Insert Table 2 here]

Among other information, the above results reveal that between 1989 and 1993 the percentage of bankruptcies was significantly higher than for the rest of the sample time period and that the percentage of bankruptcies has been decreasing gradually since 1991.

[Insert Figure 2 here]

² For further details see “Small Business Administration” (SBA). <https://www.sba.gov/>.

Table 3 shows how the 419 identified bankruptcies are distributed across industries and reveals that the manufacturing industry is the industry where there is a higher percentage of bankruptcies, 40.8%, followed by the Public Administration, Services, and Mineral industries, with 17.2%, 14.8%, and 11.2%, respectively.

[Insert Table 3 here]

Table 4 shows how the 419 bankruptcies are distributed across the Stock Exchanges where the SMEs are listed. We conclude that most of the bankruptcies are related to firms that are not listed on the NYSE, AMEX, and NASDAQ.

[Insert Table 4 here]

3.2. Regression Variables

3.2.1. Dependent variable

According to our methodology, an SME fails if it files for legal bankruptcy proceedings (i.e., chapters 7 and 11). In the Compustat database firms are classified as bankrupt if they have a “TL” footnote on the status alert (i.e., Data item STALT), indicating that the firm is in a process of bankruptcy or liquidation. Therefore, our dependent variable takes the form of a binary variable which equals “1” if a firm is classified as bankrupt and “0” otherwise.

3.2.2. Liquidity Measures

The liquidity of a stock is characterized by its resiliency, tightness, and depth. The resiliency refers to the speed at which the stock prices bounce back to equilibrium after a large trade, the tightness refers to the transaction costs, i.e., the bid-ask spread, and the depth refers to the ability of the market to absorb a large quantity of trade without affecting significantly the market price.

Following previous studies, for instance, those of Fang et al. (2009)) and Hasbrouck (2009), we select common stocks, stocks that have at least 200 active trading days in a year, and the exchange, ticker, symbol, or CUSIP does not change over the year. For the zero ratio of liquidity, we do not consider stocks where the number of missing daily returns or zero daily returns exceeds 80 per cent of the annual trading days.

3.2.2.1. Turnover Ratio

The stock turnover ratio is often used to represent the average holding period of stocks (Atkins and Dyl, 1997). It is defined as the ratio of the number of shares traded to the number of shares outstanding, and determined as follows:

$$Turnover_{i,y} = \frac{1}{D_{i,y}} \sum_{d=1}^{D_{i,y}} Vol_{i,d,y} / Share_{i,d,y} \quad (4)$$

where $Vol_{i,d,y}$ is the trading volume for stock i in day d of year y , $Share_{i,d,y}$ is the number of shares outstanding for stock i in day d of year y , and $D_{i,y}$ is the number of daily observations for stock i in year y .

The smaller the turnover ratio, the longer is the average holding periods, therefore, there is a positive relationship between the turnover ratio and the stock liquidity.

3.2.2.2. Amihud (2002) illiquidity ratio

The Amihud (2002) illiquidity ratio is defined as follows:

$$RtoV_{iy} = \frac{1}{D_{iy}} \sum_{d=1}^{D_{iy}} \left(\frac{|R_{idy}|}{V_{idy}} \right) \quad (5)$$

where R_{idy} and V_{idy} are, respectively, the return and the monetary trade volume of stock i on day d at year y , and D_{iy} is the number of observations days in year y for stock i .

This ratio measures the absolute percentage price change per dollar of daily trading volume or the daily price impact of the order flow. It measures directly the impact of a monetary unit of trading volume on the stock return and, therefore, the greater the reaction of the stock's return to a unit change in the trading volume, the more illiquid is the stock.

3.2.2.3. Florackis et al. (2011) illiquidity ratio

It has been noticed that the Amihud (2002) illiquidity ratio neglects the trading frequency dimension of stock liquidity. According to Grossman and Miller (1988), the illiquidity ratio is usually obtained based on averaged price changes and averaged trading volume from the past and, therefore, cannot answer the question of how the stock price is influenced by the sudden arrival of a large trade. In addition, Cochrane (2005) highlights the fact that the Amihud (2002) ratio is much higher for small capitalization stocks, which would mean that small capitalization stocks are automatically more illiquid than big capitalization stocks. Based on this criticisms, Florackis et al. (2011) suggest an alternative illiquidity ratio that considers the stock's trading volume instead of the stock's turnover ratio, determined as follows:

$$RtoTR_{i,d,y} = \frac{1}{D_{i,y}} \sum_{D=1}^{D_{it}} \left(\frac{|R_{i,d,y}|}{TR_{i,d,y}} \right) \quad (6)$$

where $R_{i,d,y}$ and $D_{i,y}$ are defined as above.

3.2.2.4. Zero-return illiquidity ratio

The illiquidity ratio (Lesmond et al. (1999) is based on the number of days with zero return divided by the number of trading days, determined as follow:

$$Zero_{i,y} = \frac{ZeroReturn_{i,y}}{TradingDay_{i,y}} \quad (7)$$

where $ZeroReturn_{i,y}$ is the number of days with zero return for stock i over in year y , and $TradingDay_{i,y}$ is the number of trading days for stock i in year y .

3.2.3. Control variables

Bauer and Agarwal (2014) tested the Taffler (1983) z-score model, the hazard models of (Shumway, 2001; Campbell et al., 2008), and the contingent claims model of Bharath and Shumway (2008), using a dataset comprising information on all non-financial firms listed on the London Stock Exchange over the time period between 1979 and 2009. They used the ROC curve and the information content test to assess the accuracy of each of the above models and they conclude that the hazard models are superior.

We use the hazard model of Campbell et al. (2008) as our baseline model for the estimation of the probability of bankruptcy.

4. Results

In this section we conduct a correlation test followed by an analysis of the descriptive statistics, perform a univariate analysis of each individual covariate in our list and provide our robustness tests results. We show our results for the multivariate models, for each liquidity measure and the Campbell model, and highlight the differences among models.

4.1. Correlation Matrix and Descriptive Statistics

Table 5 shows the correlation matrix for the variables in our regression model. It shows that all the correlation coefficients are statistically significant at the 5% level. Nonetheless, there is are low correlation coefficient between all pairs of variables except between the Amihud and the Florakis liquidity ratios (with a coefficient of 0.66).

[Insert Table 5 here]

In order to get a preliminary insight about any possible biases and variability that might arise among the variables in the multivariate models, we provide a summary of the descriptive statistics of the covariates used. Table 6 shows the mean and standard deviation for the bankruptcies and non-bankruptcies sub-samples, as well as for the full sample. It shows that the liquidity measures for the bankruptcies sub-sample are higher than those for the non-bankruptcies sub-sample, which is in line with our expectation that firms with more illiquid stocks are more likely to go into bankruptcy. We find that the Amihud (2002) and the turnover ratios are roughly 2.5 times higher in the bankruptcies sub-sample than in the non-bankruptcies sub-sample, the Florackis et al. (2011) ratio for the bankruptcies sub-sample is twice as that for the non-bankruptcies sub-sample, and the Zero-return ratio of the bankruptcies sub-sample is 1.5 times that of the non-bankruptcies sample.

We conclude, therefore, that the stock liquidity is a good complementary variable to be taken into account when estimating the probability of SMEs bankruptcy.

[Insert Table 6 here]

4.2. Univariate Analysis

Univariate analysis has been extensively advocated and employed in the literature to gain a preliminary insight of the discriminate power of the explanatory variables (Nam et al., 2008; Altman et al., 2010). In Table 7 we show our results for the univariate analysis estimated using the discrete hazard models for each covariate. We find that all the covariates are statistically significant in discriminating between bankrupt and nonbankrupt SMEs, and the all the covariate coefficients have the expected sign.

[Insert Table 7 here]

4.3. Discrete-time Duration-dependent Hazard Models

Table 8 shows our estimations for discrete-time duration-dependent hazard models, where the first model, includes the Amihud (2002) ratio, the second model, includes the Florakis et al. (2011) ratio, the third model, includes the Turnover ratio, and the fourth model includes the Zero-Return liquidity ratio. We use the Campbell et al. (2008) model as a baseline model where none of the above liquidity variables are included. We find that all liquidity measures have a positive relationship with the probability of failure, which indicates that less liquid stocks are associated with higher bankruptcy probability. Among all the liquidity ratios, the Amihud (2002) is the one with the highest statistical significance. In addition, the goodness of fit measures AIC and BIC, show that the Amihud (2002) model provides the best goodness of fit.³

[Insert Table 8 here]

4.4. Robustness Tests

Table 9 shows our results for the predictive ability test. We conclude that the Amihud (2002) model provides the highest classification performance, with roughly 60% discriminatory power for the top three deciles. The Florackis et al. (2011), Turnover, and Zero-return liquidity ratios provide a discriminatory power of roughly 57%, 54%, and 56%, respectively, and the discriminatory power of the Campbell (2008) model is about 54%. This means that adding a liquidity measure into the Campbell model increases its classification performance and helps to give better predictions for bankruptcy probability.

[Insert Table 9 here]

³ Note that the lower the value of AIC, the better is the model's fit.

The above findings are supported by the results provided in Figure 3, which show the area under the receiver operating characteristics curve (AUROC). The Amihud (2002) ratio has the highest within and out-of-sample AUROC, with values of 0.76 and 0.75, respectively, which show that it has a higher discriminatory performance than the other ratios. The Florakis (2011) ratio has the second best performance in terms of the robustness tests, with an AUROC value of 0.76 and 0.74 within and out of sample, respectively. The within and out of sample AUROC values for the Campbell model are the lowest among the models tested, which corroborates the view that the stocks' liquidity variable when included in the bankruptcy models, enhances their predictive power.

[Insert Figures 3-7]

5. Conclusion

Our results show that the liquidity of the stocks in the bankruptcies sample is lower than that of those in the non-bankruptcies sample. The relationship is robust across multiple liquidity measures. The Amihud's and turnover ratios are approximately 2.5 times higher in the bankruptcies sample, the Florackis ratio of the bankruptcies sample is twice as high as that of the non-bankruptcies sample, and the Zero-Return ratio is 1.5 times higher. All the liquidity ratios support the hypothesis that firms with more illiquid stocks are more likely to enter into a bankruptcy process.

Our classification performance test concluded that adding a liquidity measure variable to the model of Campbell (2008) helps to improve its predictive power. Estimation of the discrete-time duration-dependent hazard models incorporating four different liquidity ratios confirm our expectations that each liquidity measure enjoys a positive relationship with the probability of failure indicating that less liquid stocks are associated with higher probability of bankruptcy.

Table 1: Definition of the regression model variables.

Variable	Definition	Expected Sign
<i>Dependent variable</i>		
Fail	Dummy variable that is equal to one if a company enters insolvency procedures and zero otherwise.	
<i>Independent Variables</i>		
1. Accounting variables		
NIMTA	Net income to market-valued total assets (Profitability)	(-)
TLMTA	Total liabilities relative to market-valued total assets (Leverage)	(+)
CASHMTA	Cash over market-valued total assets (Liquidity)	(-)
MB	The ratio of book value of total assets minus the book value of equity plus the market value of equity to book value of assets (Market to book value)	(-)
2. Market Variables		
RSIZE	Logarithm of the firm's size over the aggregate market value of the S&P 500 index	(-)
EXRET	Logarithm of the excess return over the s S&P 500 "Return Index = RI"	(-)
SIGMA	Standard deviation of daily return over the past 3 months	(+)
PRICE	Log of Unadjusted or raw stock price and denominated in pence	(-)

Table 2: The sample distribution over time. Columns (2) and (4) show for each year the number of firms which are bankrupt and the number of firms which are not bankrupt, respectively. Columns 3 and 5 show for each year the percentages of firms which are bankrupt and not bankrupt, respectively. Column 6 shows for each year the total observations of our sample.

Year	Bankruptcies (n)	Bankruptcies (%)	Non-bankruptcies	Non-bankruptcies (%)	Full Sample
1984	11	0.96	1,135	99.04	1,146
1985	10	0.84	1,176	99.16	1,186
1986	11	0.90	1209	99.10	1,220
1987	13	0.99	1290	99.00	1,303
1988	15	0.99	1487	99.00	1,502
1989	17	1.24	1354	98.76	1,371
1990	31	2.17	1395	97.83	1,426
1991	27	1.80	1473	98.20	1,500
1992	20	1.36	1456	98.65	1,476
1993	21	1.43	1451	98.57	1,472
1994	17	1.08	1561	98.92	1,578
1995	15	0.88	1698	99.12	1,713
1996	22	1.23	1767	98.77	1,789
1997	17	0.93	1815	99.07	1,832
1998	19	0.99	1892	99.01	1,911
1999	14	0.72	1935	99.28	1,949
2000	9	0.40	2254	99.60	2,263
2001	16	0.74	2135	99.26	2,151
2002	13	0.64	2013	99.36	2,026
2003	15	0.70	2135	99.30	2,150
2004	17	0.81	2086	99.19	2,103
2005	13	0.71	1813	99.29	1,826
2006	11	0.62	1758	99.38	1,769
2007	6	0.35	1692	99.65	1,698
2008	7	0.46	1502	99.54	1,509
2009	9	0.63	1423	99.37	1,432
2010	7	0.56	1234	99.44	1,241
2011	4	0.35	1145	99.65	1,149
2012	6	0.59	1004	99.41	1,010
2013	6	0.63	945	99.37	951
Total	419	0.88	47,233	99.12	47,652

Table 3: The construction of industry-codes. The SIC codes are provided in column 1, the corresponding Industry is shown in column 2 and the respective industry names are given in column 3. In columns 4 and 5 we provide the number and the percentage of bankruptcies for each industry over the sample time-period (1984 - 2013).

IND	SIC	Industry		
Code	code	Name	Bankruptcies (n)	Bankruptcies (%)
1	<1000	Agriculture, Forestry and Fisheries	2	0.48%
2	1000 to less than 1500	Mineral Industries	47	11.22%
3	1500 to less than 1800	Construction Industries	9	2.15%
4	2000 to less than 4000	Manufacturing	171	40.81%
5	4000 to less than 4899	Transportation and Communications	9	2.15%
6	4950 to less than 5200	Wholesale Trade	15	3.58%
7	5200 to less than 6000	Retail Trade	32	7.64%
8	7000 to less than 8900	Service Industries	62	14.80%
9	9100 to less than 10000	Public Administration	72	17.18%
Total Bankruptcies			419	100.00%

Table 4: The number and percentage of bankruptcies in our sample by the Stock Exchange where the firms are listed.

Stock Exchange	Bankruptcies (n)	Bankruptcies (%)
NYSE	21	5.01%
AMEX	9	2.15%
OTC Bulletin Board	140	33.41%
NASDAQ	23	5.49%
Other OTC	226	53.94%
Total Bankruptcies	419	100%

Table 5: The correlation coefficients between the variables used in our regression models, where ***, **, and * indicate that the correlation coefficient is significant at 1%, 5%, and 10% level respectively.

	Amihud	Florakis	Turnover	Zero-return	NIMTA	TLTMA	EXRET	RSIZE	SIGMA	CASHMTA	MB

Table 8: This table reports the results of the estimations corresponding initially to the Campbell (2008) model and subsequently incorporating Amihud (2002), Florakis et al. (2011), Turnover and Zero-Return liquidity ratios. For each of this models, we report our results from the multivariate hazard analysis and the goodness of fit measures, where ***, **, * indicate that the coefficients are significant at the 1%, 5%, and 10% level, respectively.

Variable	Campbell (2008)		Amihud (2002)		Florakis et al. (2011)		Turnover		Zero-return

Table 9: The classification performance of the measures provided by the Campbell (2008), Amihud (2002), Florakis et al. (2011), Turnover and Zero-Return models, over the period between 2009 and 2013. The models with better classification performance have higher percentage at the top deciles.

Decile	Campbell (2008)	Amihud (2002)	Florakis et al. (2011)	Turnover	Zero-return
1	22.18%	26.89%	24.83%	23.71%	24.12%
2	16.52%	17.08%	17.75%	16.18%	16.97%
3	15.12%	14.30%	14.55%	14.20%	14.65%
4	12.78%	14.44%	11.83%	13.47%	12.99%
5	9.25%	9.06%	8.82%	9.07%	8.57%
6 , 10	24.15%	18.23%	22.22%	23.37%	22.70%
Total	100.00%	100.00%	100.00%	100.00%	100.00%

Figure 1: The estimated curves based on the Kaplan-Meier estimator, where the left-hand side figure (1A) represents the survival curve and the right-hand side represents the hazard curve (1B), whereas the age of firms in years is represented by the “Age”.

Figure 2: The evolution of the percentage of bankruptcies over the time period between 1984 and 2013.

Figure 3: This figure shows the Area Under the Receiver Operating Characteristics Curve (AUROC) for the Amihud (2002) model. The left-hand side figure shows the out of sample AUROC from 2009 to 2013 and the right-hand side figure shows the within sample AUROC from 1984 to 2008.

Figure 4: This figure shows the Area Under the Receiver Operating Characteristics Curve (AUROC) for the Florakis (2011) model. The left-hand side figure shows the out of sample AUROC from 2009 to 2013 and the right-hand side figure shows the within sample AUROC from 1984 to 2008.

Figure 5: This figure shows the Area Under the Receiver Operating Characteristics Curve (AUROC) for the zero return model. The left-hand side figure shows the out of sample AUROC from 2009 to 2013 and the right-hand side figure shows the within sample AUROC from 1984 to 2008.

Figure 6: This figure shows the Area Under the Receiver Operating Characteristics Curve (AUROC) for the Turnover model. The left-hand side figure shows the out of sample AUROC from 2009 to 2013 and the right-hand side figure shows the within sample AUROC from 1984 to 2008.

Figure 7: This figure shows the Area Under the Receiver Operating Characteristics Curve (AUROC) for the Campbell et al. (2008) model. The left-hand side figure shows the out of sample AUROC from 2009 to 2013 and the right-hand side figure shows the within sample AUROC from 1984 to 2008.
