Abstract

Introduction: Human respiratory syncytial virus (RSV) is a common respiratory virus that causes severe lower respiratory tract infection in infants, children and aged adults. Currently, there is no active prophylaxis present in the market for RSV infection; however, there are over a dozen compounds being tested in the laboratory as well as clinical trials. To increase the efficiency and safety of these therapeutics, there is a need for delivery vehicles.

Areas covered: Liposomes can be used for delivering anti-RSV agents with the advantage of modulating and eliciting the desired adjuvant effect by the different combination of lipids. This review discusses the promising application of liposome for anti-RSV therapeutics.

Expert opinion: Liposomes are attracting attention for delivery of pulmonary therapeutics, since they offer compatibility for delivering drugs, vaccines and other therapeutic molecules. Variation in liposome size and composition gives flexibility for the amount and number of deliverables, whilst targeted delivery with the capability for immunomodulation makes liposomes a promising candidate for RSV therapeutic applications.

Keywords: RSV, liposomes, lipids, peptides, small molecules, drugs
Article highlights

- Currently, broad spectrum antiviral drug ribavirin and palivizumab (monoclonal antibody) are solacing measures against RSV infection. However, there is no effective prophylaxis or treatment available for RSV infection.
- There are several potential therapeutic candidates in pre-clinical and clinical trials and their efficacy can be enhanced by using effective delivery vehicles.
- There are many drug delivery systems available; however, liposomes are the most successful drug delivery vehicles in the market. Application of liposomes for RSV drug delivery is largely unexplored.
- Liposomes offer versatile ways of loading polar and non-polar therapeutic candidates. Modulating liposome synthesis chemistry not only allows controlled release but also targeted delivery of cargo. These characteristics of liposomes are desirable for targeting lung pathogen like RSV.
- Liposomes may stimulate immune system and can be a favorable when delivering vaccines. Modulating pharmacokinetics and pharmacodynamics events of a drug could be achieved by liposomal drug delivery.
- An overlapping perspective of RSV pathology, therapeutics and liposome engineering is crucial in development of RSV vaccine and drugs and needs to extrapolate this multidisciplinary approach.

1. Introduction

An attentive basis of the respiratory tract infections such as bronchitis and pneumonia is generally respiratory syncytial virus (RSV). Worldwide, RSV is the leading cause of acute lower respiratory tract (LRTI) infections [1]. It is a negative sense ssRNA virus, which belongs to the order Mononegavirales and Pneumoviridae family. The transmission of RSV is primarily through air droplets from infected individuals or indirectly through fomites [2]. RSV infection is conspicuous during winter on populations including all age groups from fetus and infants [3] to older adults [4]. For the year 2015,
the globally estimated incidents of RSV associated LTRI in children below 5 years was about 33.1 million, which resulted in 3.2 million hospitalizations and 59600 in-hospital mortalities [5].

Moreover, 45% of hospitalization and in-hospital deaths of children below the age of 6 months is caused by RSV associated LTRI, with RSV frequently the basis of respiratory tract infections such as bronchitis and pneumonia [5]. In the USA, thousands of hospitalizations and over 2 million hospital visits were recorded between the years 2014-2017 for RSV infections.

Initially, the RSV invades nasopharyngeal epithelium causing mild upper respiratory tract infection (URTI) and may progress to potentially precarious LRTI by intracellular transmission, where most of RSV replication is dominant [6]. The infection causes severe bronchitis and respiratory discomfort like apnea. Since the natural infection is not capable of educating life-long immunity, the individuals affected are prone to repeated RSV infection [7]. Furthermore, there is currently no vaccine available for prophylaxis and, whilst the broad-spectrum antiviral drug ribavirin is used for treatment, its clinical efficacy is variable. Although Palivizumab - a humanized monoclonal antibody against RSV – represents a helpful option to be prescribed for high-risk individuals, this comes at a high cost [8]. As such, the treatment for RSV is generally limited to supportive measures, including drugs to reduce the inflammation and antibiotics to reduce the risk of bacterial infections.

Consequently, the need for prophylaxis and an effective treatment regime against RSV is imperative. Currently, there are approximately 20 anti-viral drugs, and over 12 vaccines are in clinical trials [9]. A common limitation in anti-RSV therapeutic product development is that therapeutics often suffer from early degradation or body clearance and may cause undesired effects such as toxicity. These issues can be resolved by encapsulating the therapeutic agents within nanocarriers, which protects the therapeutic agent from degradation and offers advantages of controlled release and effective delivery [10, 11, 12]. Several materials for nano-deliverables like chitosan, poly (lactic-co-glycolic) acid, polylactic acid and poly (2-hydroxyethyl methacrylate) [13, 14] have been explored against RSV. However, liposomes, which are widely used for drug
delivery and have also been approved and marketed for human use, are yet to be fully exploited for RSV [15]. The potential of liposomes as a carrier of active therapeutic agents was described decades ago [16, 17, 18], while liposomes have attracted much attention for their ability to carry antigens as well as immunomodulators [19]. They can express adjuvant action by enhanced antigen delivery or inducing innate immune responses [20]. Liposomes have been used widely for various diseases and disorders; some are in clinical trials, while others have made the market [21]. This indicates the significance and promise of liposomes for drug delivery. Here, we present the relevance and promise of liposome-based nanoparticulate systems for vaccines and drugs against RSV.

1.1 Infection of the respiratory tract by RSV

1.1.1. RSV life cycle

RSV has a single-stranded 15,222 nt long RNA genome encoding 11 proteins including 2-non-structural proteins (NS-1 and NA-2), 3-surface proteins (glycoprotein-G, fusion protein-F, and small hydrophobic protein-SH), two overlapping frames of M2 mRNA produce 2 distinct matrix proteins (M-1 and M-2) and 4 other structural proteins (matrix protein-M, nucleocapsid-N, phosphoprotein-P and large protein-L) (Figure 1) [6, 22]. The viral envelope of the RSV has three membrane proteins, namely G, F, and M (Figure 1). A successful RSV life cycle is an interplay of viral and cellular components that eventually favors viral replication and establishment of infection (Figure 2). RSV infection initiates with the attachment of viral G protein to cellular proteins like CX3CR1 [23], surfactant protein A [24], or annexin II [25]. The entry of virion particle into the cell is determined by the critical step of virion and cell membrane fusion carried out by RSV F protein. The nucleolin protein acts as a receptor for RSV F protein [26]. The trimeric F protein changes conformation, facilitated by six-helix bundles, to fuse the virus and cell membrane [27]. The F and G proteins are conserved and candidates for vaccine and drug development. The viral disassembly and release of RNA genome facilitates transcription of mRNA and translation of proteins; on the other hand, the anti-genome enables more viral RNA genome copies to be made. The viral proteins then assemble
along with the genome in the cytoplasm or cell membrane to release new viral particles or filaments [28, 29].

1.2. Therapeutics for RSV

1.2.1. Current research on prophylaxis and treatment for RSV infection

Considering published outcomes related to treatment, as well as the impact of RSV on global healthcare, a promising treatment or vaccine development remains a priority. The viral replication by itself is not as harmful as the inflammation due to the infection; the infection leads to a complex immune response and, therefore, developing vaccines has been a challenge. The formalin-inactivated vaccine was launched in the 1960s and later withdrawn due to poor immunogenic response as well as atypical T\textsubscript{H}2-type response, increasing chances of reinfection with similar or deadly infections [30]. Attaining the balance between immunity and viral attenuation is very difficult. Therefore, developing a live attenuated vaccine for RSV is the primary goal for many researchers [31]. Clinical trials have demonstrated that intranasal administration of the vaccine restricts viral replication in infants after second dose [32]. There is more than half a dozen live attenuated vaccines under trial [32, 33, 34]. A live-attenuated vaccine \textit{cpts}-248/404 was administered intranasally, tested in phase 1 trials [33]. In this trial, a total of 114 children, out of which few were <2-year-old infants were targeted. Unfortunately, the vaccine \textit{cpts}-248/404 was found infectious and was mostly immunogenic for the children above the age of 6 months [33].

The genome of the RSV is comprised of immunogenic proteins and this creates scope to develop DNA, subunit and other nano vaccines [13]. These vaccines can be designed as carrier-based vaccines, through the use of nanoparticulate systems, such as liposomes, that can express adjuvant action by enhanced antigen delivery or inducing innate immune responses [20].

On the other hand, for the treatment of RSV infection, the only approved product against RSV infection is ‘Palivizumab,’ which is a humanized monoclonal antibody targeting the RSV [35, 36]. The first line treatment of RSV infection is the use of
bronchodilators, such as α and β adrenergic agonist [6]. For pediatrics, since corticosteroids are not approved for treating RSV infected individuals less than 1 year old due to safety concerns [37], the use of vaporub and non-aspirin formulations, such as paracetamol, are the treatments of choice prior to clinical attention. Of the very few options available for the treatment of RSV, ribavirin, a broad spectrum antiviral drug, is used, although this too comes with limitations and drawbacks such as mutagenicity, teratogenicity as well as carcinogenicity [13, 38]; despite several concept studies claiming effectiveness of ribavirin in significantly reducing the RSV load and minimizing disease severity, the disadvantages of mutagenicity, teratogenicity and carcinogenicity subsequently resulted in FDA denial [39]. However, along with just a couple of L-protein inhibitors, there are Over 20 candidates that are currently under clinical and preclinical research have been found targeting RSV fusion protein (Table-1) [40] and liposomes has been considered as delivery vehicle for few of these candidates that are undergoing in-vitro studies [41, 42, 43]; very recent research demonstrated that liposomes can become a carrier for the anti-RSV fusion peptide [15].

Similarly, and mainly for the peptide, the liposomal delivery system could play a vital role in RSV vaccine design. A benzimidazole derivative JNJ-2408068 was reported to be a potent inhibitor of RSV, but due to the limited extrapulmonary distribution, the development was halted [44, 45]. In such cases, to elicit the immune response the candidates such as adjuvants could ease the distribution and provide long-lasting immunity [46]. One of the adjuvants based RSV F vaccine is under phase 3 clinical trials [47, 48].

However, one of the challenges in using liposomes as a delivery vehicle is overcoming the strong hydration forces acting on the bilayer when the bilayer comes at a distance less than 20 Å [49]. Hence, the fusion proteins, due to their characteristics, have become attractive to the researchers as they can be vital in one or all steps of delivery or fusion process. The possibility of using lipid in RSV vaccine design was patented in the late 90s [50]. The activity of the vaccine and vaccine composition can be enhanced using modulators like adjuvants, simple organic molecules and mechanical means, such as heating antigen [51]. Liposomes can be used as adjuvants [10, 19, 52]. Designing a protein based liposomal adjuvant vaccine could be an approach to attain
maximum efficacy and low toxicity [53]. Based on the establishments in the protein-based liposomal adjuvant vaccine, protein and peptides ranging from 0.1 µg to 100 µg can be used in the vaccine designing; whereas the use of an excess carrier is recommended to achieve maximum payload [50].

1.3. Current non-liposomal delivery methods for RSV

Different biomaterials and synthetic polymer-based cargo delivery systems have been used for RSV therapeutics. Drug and vaccine delivery for RSV using these non-liposomal delivery methods have made attempts to improve the balance of delivery of cargo and safely elicit an immune response or inhibit the virus. The approach of using cargo itself is the delivery particulate system; a popular example of this is the virus-like particles (VLP), which have garnered tremendous interest among RSV vaccine development [85, 86, 87, 88, 89]. Although this is not directly in the scope of this review, it is worth mentioning. Novel drug delivery systems (NDDS) have given new insight into the medical treatments due to their unique abilities to enhance therapeutic effect and reduce toxicity [90]. Size of the particles is responsible for the permeability, retention and immune response [91]. Hence, the nanoparticulate delivery systems are preferred by many researchers around the globe to achieve enhanced permeability and retention (EPR).

These delivery methods can be broadly divided into metallic and non-metallic nanoparticles. A novel approach to inhibit RSV was the use of gold nanoparticles (GNPs). These GNPs can be functionalized with nucleic acid, antibodies, drugs, as well as with peptides, and these functionalized GNPs can then be applied in diagnosis or treatment [92]. Similar to the gold nanoparticles but different in shape are the gold nanorods. Gold nanorods can accumulate into the extracellular matrix (ECM), taken up by phagocytosis and trigger TLR signaling pathway [93]. After gold, silver is the metal that has been studied extensively by researchers for a variety of purposes. Silver nanoparticles conjugated with recombinant RSV fusion protein has also been reported to bring anti-RSV effect [94].

There are a variety of non-metallic materials that have been considered to produce particulate delivery systems. Cationic particles of chitosan are biocompatible, biodegradable and a proven vaccine carrier [13]. Enhanced delivery of RSV DNA vaccine was observed using chitosan nanoparticles when compared to naked DNA [95]. Composite chitosan gene delivery systems can be produced with the addition of polymers such as poly (2-hydroxyethyl methacrylate) [92] and alginate [96]. PLGA
nanoparticles have also been used as a carrier of F-protein delivered intranasally and intra-gastrically [97]. Compared to the chitosan and PLGA particulate system, the silica-based particulate system is less explored. Mesoporous silica is shown to have adjuvant-like properties [98], low toxicity [98, 99] and can be given orally [98]. Lutz and colleagues have recently reported ‘nanogels’ as a biodegradable carrier of covalently linked imidazoquinoline (IMDQ) TLR7/8 agonist to treat RSV [100]. A carrier similar to the liposome used in the treatment of RSV is ‘niosome.’ Niosomal structures resemble liposomes, but are vesicles of non-ionic surfactants. Asthana and colleagues have used niosomes to encapsulate clarithromycin, which is a broad spectrum, second-generation macrolide antibiotic used in the treatment of respiratory tract infections [101]. Another type of particulate system called ‘dendrimer’, a structure of repeatedly branched molecules, has also been discovered to be beneficial in the treatment of RSV infection [102]. Similar to dendrimers, micro and nano particles can be prepared from multilayered amino acids; these particles can encapsulate anti-RSV proteins in their hollow-shell structure [103].

1.4 Why liposomes for RSV?

Liposomes were first discovered by Bangham and colleagues and described as swollen phospholipid systems [104]. The application of liposomes in drug and vaccine delivery was first proposed by Gregoriadis [52]. Liposomes are composed of lipids, that when forced into an aqueous environment, align to form bilayered vesicles, which can be single or multi-lamellar and can be prepared in the range of approximately 50 nm to several microns (Figure 3). Liposomes for drug delivery have existed as marketed products for many years; brands like Ambisome®, DepoDur™, Depocyt®, Doxil®, Mepact® are a few examples. Now, liposomes are established suprastructures in vaccination [105]; Epaxal® and Inflexal® V for hepatitis A virus and Influenza virus [21], respectively, demonstrate the relevance of liposomes for therapeutics against viral pathogens. In spite of the establishment of liposomes as vaccine delivery systems, studies of promising liposomal vaccines against RSV are still under research.
The history of using liposomes for RSV vaccine systems has been fascinating; in the early 90s, Connor and colleagues described that the recombinant vaccine with M-protein could challenge RSV by inducing CD8+ T cells mediated immune response; whereas, the G and F-protein vaccine challenges RSV through the immune response caused by antibodies [106]. There are random possibilities in the case of G and F-protein vaccines; one of which is that the observed RSV resistance could have been through the mucosal IgA antibodies, whereas the other could have been an unknown factor assisting these antibodies to deplete the CD4+ or CD8+ T cells. However; in contrast to this, it was reported that the M-protein vaccine challenging RSV did not induce the serum neutralizing antibodies and purely revoked by depletion of CD8+ T cells. Apparently, based on this, a soluble G-protein fragment of the RSV was encapsulated in dioleoyl phosphatidylcholine (DOPC) liposomes to induce immunization against the RSV [42]. In the extensive research by Huang and colleagues, they have found that a fusion product of soluble fragment of the G-protein of RSV and thioredoxin protein from the *Deinococcus radiodurans* bacterium can be encapsulated into the liposomes made of the lipid DOPC alone or in combination with the lipids originated from the radiation-resistant bacterium, *Deinococcus radiodurans*, which are unique in nature and are capable of inhibiting growth of RSV [43].

Moreover, in their research, they have found that the liposomes made up of the lipid DOPC in combination with lipid 7 (α-Galactosylphophatidyglyceroylalkalamine) isolated from the total lipids of *Deinococcus radiodurans* bacterium and having the G-protein and thioredoxin protein fusion product was prominently effective against RSV. It was reported that the RSV has no cytotoxic T cells epitope [106]; therefore, the inhibitory effect of G-protein of RSV and thioredoxin protein fusion product is due to liposomes which were taken up by antigen presenting cells. This suggests that the liposomes not only can become a carrier for the vaccine but also can exert an adjuvant effect.

Alveolar macrophages have a vital role in the prevention of RSV infection as they produce an innate immune response facilitated by pro-inflammatory cytokines, for example tumor necrosis factor (TNF) [107]. During the last decade, an exciting finding came into focus, which described encapsulation of RSV antigen inside liposomes and
the prompt incursion of the neutrophils. However, the influx of neutrophils was doubtful and possibly due to reasons such as to clear the debris of dying macrophages or in response to the macrophages engulfing the liposomes [108, 109]. However, depletion of macrophages was markedly observed post-administration of liposomes encapsulated with viral antigen [108]. A possible reason could be that the alveolar macrophages differentiate in presence of surfactant and lipids are surface active agents [110]. Geall and colleagues had designed self-amplifying RNA vaccine using the lipid nanoparticles, which also can be called liposomes [111]. Subcutaneous (S.C.) administration of these lipid nanoparticles produce an innate immune response, but the reason for using low surface charged lipids seems unclear. However, use of liposomes can stabilize the RNA for long-term and can eliminate the risk of new infections caused by carrier-based vaccine [111, 112]. This finding matches with the research by Lee and colleagues, where they had observed that liposomes could deplete the macrophages. Based on their results, the study seems promising, but their research also states that the pathological features of RSV in mice and human are different [112]. So, the benefit of doubt persists with this promising study in the quest of RSV vaccine research.

A recent discovery describes that the heparin octasaccharide decoy liposomes hold the potential of inhibiting cellular attachment of some pathogens, including RSV [113]. The research describes that the decoy receptors functionalized with the heparin sulfate bind to the pathogens and thereby the pathogen cannot further bind to susceptible cells. However, although the functionalized liposomes have inhibited the cellular attachment, they were not able to stop the replication of RSV through infected cells and syncytia formation. Moreover, heparin sulfate, due to its anticoagulant nature, may be an issue to be used as an anti-viral agent.

Research has also has come forward recently where the RSV small hydrophobic (SH) protein can be targeted by using an inhibitor known as ‘pyronin B’ [114]. Small hydrophobic protein is a small 64-amino acid encoding peptide. Although the role of the small hydrophobic proteins in RSV infection is not well understood, Li and colleagues had found that the pyronin B binds the small hydrophobic protein from the lipid face and not from the pore lumen. Binding in this region blocks the small hydrophobic protein channel and thereby inhibits the growth of the RSV [114]. Interestingly, the binding of
pyronin B was concluded from a liposome-based assay, where the small hydrophobic protein was encapsulated into the liposomes, and the attachment of this protein was confirmed by nuclear magnetic resonance (NMR) spectroscopy. Here, it would have been interesting to see whether the pyronin B encapsulated into the liposomes can exert some effect in comparison with the pyronin B alone.

Alternatively, liposomes can be designed to look like a virus and known as virosomes [115] and are virus without a genome. Inhibition of RSV infection was recently observed with the virosomes made of 1,2-dihexanoyl-sn-glycerol-3-phosphocholine (DCPC), egg phosphatidylcholine (PC) and egg phosphatidylethanolamine (PE) were used to immunize the mice and challenged with live RSV [7, 115]. Kamphuis and colleagues have reported that immunization of mice with lipid made virosomes shown to have increased level of virus neutralizing IgG2a antibodies and IFN-γ expression [7].

1.5 Lipids used for RSV inhibition

Approximately 90% of the pulmonary surfactant composition is lipids [116, 117]. In recent years, names of various lipids have appeared in the research for treating the RSV infection; for example, Numata and colleagues have mentioned that the inhibition of RSV is possible by the phosphoinositol (PI) surfactant lipid [117] and have classified phospholipids as major and minor; the PC is considered as the major, whereas the PI and PG are regarded as minor. In the same research, Numata and colleagues explain that the PI lipid stops the RSV spread by blocking the RSV to cell attachment and not by acting on virus directly; whereas, approximately 20% reduction in percentage plaque numbers was observed when treating RSV with PC lipid [117]. However, the mechanism of action of PG also involves blocking virus-cell attachment [118, 119] but the lipid PG is found to be less effective than PI [116, 117]. Referring to their research, it can be concluded that both major and minor lipids are capable of stopping RSV spread to an extent, although the mechanism of action is different.

In the past, researchers have mentioned the virucidal effect of glycerides and fatty acids against RSV [120, 121]. Hilmarsson and colleagues have noted that, without
changing they hydrophilic-lipophilic balance (HLB) value and merely changing the pH from neutral to acidic, the virucidal activity of the compound is increased [120]. Surprisingly, steroids and carotenoids are ineffective against RSV infection [122, 123], but other derived lipids, such as terpenoids, are being considered as potential anti-RSV agents [124].

Table 2 Lipids used for RSV inhibition and the proposed activity of the lipids towards RSV. (PC= Phosphatidylcholine, PI= Phosphatidylinositol, PG=Phosphatidylglycerol).

1.6 Selection of lipids for liposomal formulation

The formation of liposomes can be described as a two-step process; the first step is bilayer formation and the second is the closing of the bilayer to form liposomes. The transition temperature of lipids is responsible for their phase change, and lipids, when at temperatures above their transition temperature, will initially orientate into parallel alignment and form a sheet-like structure; subsequently, liposomes form by the bilayer sheet closing onto a vesicle structure to reduce tension [126].

Increasing the hydrophobic chain length of lipids increases their transition temperature. Transition temperature (Tc) plays a crucial role in the formation, as well as
membrane fluidity of liposomes [127]. The lipid transition temperature is the temperature
where the lipid changes its phase from an ordered solid state of lipid to disordered liquid
crystalline state. In the ordered solid state, the hydrocarbon chains are extended and
packed; whereas in the disordered state, the chains are randomly oriented.

In consideration of their application, the liposomal transition temperature is a key
factor. Employing lipids with transition temperatures about body temperature (>37°C)
make lipid bilayers less prone to leakage and uptake by the MPS at physiological
temperature [128]. On the other hand, liposomes with lower Tc (<37°C) are more
susceptible to leakage at physiological temperature and may experience quick uptake
by MPS or lose their original structure at that temperature [129, 130]. The long
saturated alkyl chains result in higher transition temperature, and this property is
beneficial for drug retention in vivo. For example, DSPC shows better drug retention
compared to 1,2-dipalmitoyl-sn-glycerol-3-phosphocholine (DPPC) [131]. Furthermore,
the long saturated chains of DSPC increase the probability of high drug loading,
especially for lipid soluble drugs [11, 12]. Although there are a variety of lipids that have
been reported, the use of PC lipid can be seen prominently in the marketed formulations
(Table 3).
Table 3 Name, therapeutics and composition details of the marketed liposomal formulations. 1.7 Prospective of liposomes in designing prophylaxis for RSV infection

So far F, G, M, and small hydrophobic proteins have been identified as targets to avoid the RSV infection [42, 106, 113, 114]. However, the role of F-protein is vital in the spread of the virus because targeting the G-protein can neutralize the virus, but the actual spread of the virus is only possible after inhibiting the F-protein [50]. Over a decade ago studies were suggesting that all three F-G- and RSV-SH protein inhibitors are required for complete success [132]. However, in the last decade researchers have realized the potential of F-protein for inhibiting RSV infection [133, 134]. Therefore, some recent studies have specifically targeted the F-protein [59, 60, 83]. The F-protein is structured in 9 domains; namely, signal peptide (SP), fusion peptide (FP), heptad repeat (HR) 1 & 2, transmembrane anchor (TM), cytoplasmic tail (CT), domain of 27 amino acids peptide (p27) and finally the F1 as well as F2 subunit domains [66]. The F-protein can be synthesized as an inactive precursor (F0) having 574 amino acids that can be cleaved at C-terminal and N-terminal yielding F1 and F2 subunits, respectively [135]. Compounds can be designed to target the subunit regions which assist the fusion peptide’s attachment to the host cells [60]. Perron and colleagues had tested a variety of compounds that target the F-1 subunit of the F-protein explicitly. One of these molecules, called GS-5806, was found to be a potent inhibitor of RSV with minimal toxicity and is undergoing phase-2 clinical trials. However, other compounds failed to meet the toxicity results achieved from the GS-5806. For these compounds, delivery systems like liposomes or nanoparticles could help lower the toxicity and achieve the desired physiological effect. For example, it is reported that liposomes not only can carry inhibitory protein GS-5806, but also help in triggering the fusion process and facilitating the RSV inhibition [59].

Liposomal research to date describes them as a system that can be used not only as a delivery system but also as adjuvants [10, 20, 52]. Liposome-based vaccine systems can be designed based on the type of immune response to be achieved; for example, MLV or LUV for TH1 immune response and SUV for the TH2 immune response [20, 136]. Moreover, There are eight fundamental ways of using liposomes as drug delivery vehicles and hence, liposomes are multifaceted delivery systems (Figure 4) [137] and are capable of co-encapsulating compounds depending on their
characteristics [138]. This structural attribute of liposomes can co-encapsulate compounds [138] and become a carrier of multiple proteins and other anti-RSV compounds. Liposomes can be designed to look like a virus by attaching various proteins to it [139]. Therefore, liposomes can be called 'multifaceted delivery systems' and hold the potential of entering the mainstream for designing the prophylaxis against RSV infection.

2. Expert opinion

Liposomes cover a variety of therapeutic areas including viral vaccine, cancer therapy, fungal diseases and analgesics, with more than a dozen liposome formulations already marketed and many are in clinical trials. Liposome formulations suit all ages including infant and older adults [140]. Since more than 90 % of pulmonary material is a lipid, these lipid vesicles should not interfere with the functioning of the respiratory system. Moreover, many researchers have shown liposomes to be non-toxic [141, 142]. Therefore, liposomes being the most successful delivery system are now being considered as a carrier for many anti-RSV agents.

With no prophylaxis measures, RSV infection can become severe to lethal for prematurely born babies, children, and older adults. There is a need of immunoprophylaxis or anti-viral therapy to curtail increasing rates of hospitalization and mortality. In the development of a vaccine, the fate of vaccine depends on various stages, such as good laboratory practice (GLP), good manufacturing practice (GMP), good clinical research practice (CGRP) as well as the post-licensure studies. Of course, precise regulatory submission, statistical data analysis, and environmental factors contribute to an extent too [143]. At present, many anti-viral drugs, as well as monoclonal antibodies, are undergoing clinical trials. For the anti-RSV agents, liposomes can become a carrier to bring essential therapeutic effect with reduced toxicity.

Liposomes, due to their structural attributes, can encapsulate drugs within the bilayer, hydrophilic core or certain agents can be adsorbed/anchored on the surface of the liposomes. Therefore, consideration of co-encapsulation of the hydrophilic and
lipophilic component, along with anchored ligands, could be the maximum usage of the structure of the liposome. Formulation of liposomal suspension with uniform vesicle distribution and minimal batch to batch variation is challenging but possible with precise manufacturing practice and quality ingredients. Further, the analysis of liposomal suspension has a variety of aspects to consider, such as percent encapsulation, size, surface charge, stability, and toxicity. Modern techniques like microfluidics can deliver uniform particles with higher encapsulation efficiency [144]. The stability of the liposomal suspension is can be customized for controlled release of the cargo based on the selection of the lipid composition. It is recommended that longer chain lipids with a high transition temperature (Tc) to be incorporated into the liposomal formulation for better encapsulation and extended stability [145]. For instance, palivizumab used in the RSV treatment, encapsulation of this drug into the higher Tc lipid could make the formulation stable by limiting the release of the drug on storage and may reduce its toxicity. Encapsulation of peptides is also considered challenging as many of the peptides are temperature sensitive. In such cases, considering a composition of different transition temperature lipids is recommended. Doing this will not only verify the trend of stability of the formulation but also will assist to match the anti-viral effect with the drug loss. On the other hand, selection of lipids is very important in designing anti-viral liposome formulations, as certain lipids have shown anti-viral properties. Therefore, selection of such lipids would be a booster, in addition of the effect of the anti-viral agent. This can be also enhanced by using lipids that have immunomodulatory effects. The choice of synthesizing liposomes for the vaccine should complement the immune response elicited by the vaccine, tailoring liposomes for adjuvant or immuno-stimulatory effect dependent on the cargo to balance and generate desirable protection against RSV.
Funding

The funding to publish this review article was from the grant NSF-CREST-(HRD-1241701).

Declaration of interest

The authors have no relevant affiliations or financial involvement with any organization or entity with a financial interest in or financial conflict with the subject matter or materials discussed in the manuscript. This includes employment, consultancies, honoraria, stock ownership or options, expert testimony, grants or patents received or pending, or royalties.

Reviewer disclosures

Peer reviewers on this manuscript have no relevant financial or other relationships to disclose.

Acknowledgements

We would like to thank Ms. Eva Dennis for helping us with artistic work related to figures.
