ABSTRACT

1

Peanut allergy (PA) currently affects approximately 2% of the general population of Western nations
and may be increasing in prevalence. Patients with PA and their families/caregivers bear a
considerable burden of self-management to avoid accidental peanut exposure and to administer
emergency medication (adrenaline) if needed. Compared with other food allergies, PA is associated
with higher rates of accidental exposure, severe reactions, and potentially fatal anaphylaxis.
Approximately 7-14% of patients with PA experience accidental peanut exposure annually, and one-

8 third to one-half may experience anaphylaxis, although fatalities are rare.

10 These risks impose considerably high healthcare utilisation and economic costs for patients with PA 11 and restrictions on daily activities. Measures to accommodate patients with PA are often inadequate, 12 with inconsistent standards for food labelling and inadequate safety policies in public establishments 13 such as restaurants and schools. Children with PA are often bullied, resulting in sadness, humiliation, 14 and anxiety. These factors cumulatively contribute to significantly reduced health-related quality of 15 life for patients with PA and families/caregivers. Such factors also provide essential context for risk/benefit assessments of new PA therapies. This narrative review comprehensively assessed the 16 17 various factors comprising the burden of PA.

18

19 Keywords: Accidental exposure, anaphylaxis, burden, health-related quality of life, peanut allergy

20

21 INTRODUCTION

22

Peanut allergy (PA) is one of the most common food allergies among children in Western nations,¹
and is often a lifelong condition.² Onset of PA typically occurs in early childhood,³⁻⁶ and is associated
with more severe reactions than other food allergies.⁷ In contrast to food allergies such as milk, egg,
wheat, and soy that resolve in childhood or adolescence in approximately half to the majority of
cases,^{8,9} PA persists into adulthood in approximately 75-80% of children.^{2,10}

2 Until recently, the recommended management strategy for PA was limited to the combination of strict 3 allergen avoidance along with an action plan, including having an adrenaline autoinjector (AAI) on hand in case of accidental exposure and reaction to peanut,^{11,12} which is sometimes referred to as an 4 avoidance management strategy.¹³ However, the 2018 European Academy of Allergy and Clinical 5 6 Immunology (EAACI) Guidelines for management of food allergy recommended oral immunotherapy (OIT) as a treatment option to increase the reaction threshold in children with PA from around 4-5 years of age (strength/evidence level/grade of recommendation: strong/1/A) (Supplemental Table 1).¹⁴ 8 EAACI guidelines further stated that post-discontinuation effectiveness of OIT is suggested, but not 9 10 vet confirmed.

11

1

The combined factors of the risk of potentially life-threatening and often traumatic accidental allergic 12 13 reactions, lifelong persistence of PA in the majority of individuals, responsibility for self-management of risks, and the lack of any approved treatments for this condition, all contribute to a significant 14 burden of illness associated with PA.^{15,16} Multiple studies have investigated specific aspects of the 15 burden of PA, such as impact on health-related quality of life (HRQoL),¹⁷⁻¹⁹ risks of accidental 16 exposures to peanut,²⁰ and costs of self-management of PA.²¹ However, comprehensive reviews that 17 assess these various factors together to provide an updated and holistic perspective on the burden of 18 19 PA are lacking. Such perspectives are particularly needed in light of recent evidence that PA incidence and prevalence may be increasing,^{8,22} thus potentially adding to the societal burden of PA. 20

21

22 These perspectives are particularly relevant due to recent advances in PA management, which pose 23 new choices and important questions for clinicians, patients with PA, and their caregivers. Recent 24 clinical trials have demonstrated the benefit of introducing peanut to children at a young age to reduce the risk of developing PA,²³ prompting the publication of US, British, and Australasian guidelines for 25 early introduction of peanut to infants/at-risk infants.²⁴⁻²⁶ In addition, the novel oral immunotherapy 26 27 Peanut (Arachis hypogaea) Allergen Powder-dnfp, formerly known as AR101, was recently approved 28 to mitigate allergic reactions that may occur with accidental exposure to peanuts in individuals 4-17 years of age with a confirmed diagnosis of PA.^{27,28} Other immunotherapies are in phase 2 and 3 29

development.²⁹⁻³¹ A complete and accurate assessment of the current burden of self-managed PA is
 needed to allow for full consideration of the role of emerging and future management options.

4 **Objective**

This article will review in comprehensive narrative format the impact of the risks of PA and the burden of self-management on peanut-allergic children, adolescents, and their families.

Methods

9 Narrative review vs. systematic review

10

3

5

6

7

8

11 This narrative review was designed to assess the latest data concerning the burden of PA from a broad 12 and multifaceted perspective, including impacts in socioeconomic, clinical, psychosocial, and HRQoL 13 domains. Because narrative reviews are generally comprehensive and cover a wider range of issues 14 within a given topic, as compared to the narrow focus and prescribed methods of a systematic review, 15 the use of a systematic or meta-analysis review method was deemed impractical for the purpose of 16 assessing the spectrum of factors associated with PA burden. Additionally, since multiple individual 17 searches were required for each topic, using consistent, precise selection/elimination criteria across 18 topics would have inherently resulted in the omission of several publications that were critical to our 19 report.

20

21 We searched the United States National Institute for Biotechnology Information/National Institutes of 22 Health/National Library of Medicine PubMed database (https://www.ncbi.nlm.nih.gov/pubmed) for 23 studies pertaining to the burden of PA in the following main keyword/topic areas: peanut allergy 24 prevalence and incidence, accidental exposures, anaphylaxis and severe reactions, healthcare 25 utilisation, economic costs, mortality, comorbidities, burden of peanut allergy on the individual and 26 family (including requirements of disease self-management), and peanut allergy impact on HRQoL. 27 The searches for each topic area, search terms used for each, and main results of each search are 28 illustrated in Supplemental Figure 1. Initial searches were limited to data published within the past 2 29 years. If these data were insufficient, we conducted a second search within a 10-year time frame. We

also incorporated articles as appropriate if publications retrieved during our searches pointed to
 essential prior studies.

4 **RESULTS**

3

5

12

Peanut Allergy Prevalence And Incidence

Estimates of PA prevalence have varied in part due to the different methods utilised for determining
its presence, ranging from self-report to skin prick test (SPT), peanut-specific immunoglobulin E
(psIgE) testing, and oral food challenge (OFC), as well as different thresholds for each test, and the
age cohorts and regional populations studied. Some evidence also suggests incidence and prevalence
of PA may be increasing, thus introducing a further challenge to accurate assessment.^{8,32} Studies
reporting prevalence of PA published since 2010 are listed in Table 1.

13 Overall, studies have generally reported PA prevalence rates between 1% and 2% in Western nations (Table 1). Incidence and prevalence of PA appear to be less common in Asia and other global areas, 14 although epidemiological studies of PA in non-Western regions have been sparse (Table 1).²² One 15 cross-sectional, multicenter study reported a PA prevalence of 0.8% in South African children based 16 on SPT and OFC,³³ and a cross-sectional study in Kuwaiti schoolchildren aged 11-14 years reported a 17 PA prevalence of 1.3% based on clinical history.³⁴ A retrospective, single-center cohort study found 18 19 that among 98 Singaporean children presenting with anaphylaxis, peanut was the most common 20 trigger of anaphylactic events, although no cases of peanut-triggered anaphylaxis were documented in 21 a similar study conducted 15 years earlier, possibly indicating effects of changes in dietary habits.^{35,36} 22 In both studies, anaphylaxis cases were indicated by hospital and emergency room discharge codes 23 and confirmed by presence of clinical symptoms; however, the later study used the 2008 Sampson 24 criteria for diagnosis, while these criteria were not available for the earlier study.^{35,36}

25

Some, but not all, data also indicate that PA incidence and prevalence may be increasing in Western nations.^{3,37,38} A longitudinal national US claims database study found that annual incidence of PA in one-year-old children had increased from 1.7% in 2001 to 5.2% in 2017.³⁹ A recent study in a representative US population of over 40,000 individuals found that PA impacts 2.2% of children and

1.8% of adults.^{40,41} In addition, a retrospective cohort study of children aged 0-6 years in the
 Australian Capital Territory reported increasing incidences of PA (children born in 2001, 0.73%;
 children born in 2004, 1.15%).⁴²

5 Among prevalence studies, a nationwide US study found a 3-fold increase in self-reported PA prevalence in children between 1997 (0.4%) and 2008 (1.4%),³⁷ although actual prevalence figures 6 may be inflated in studies only considering self-reported PA.^{8,43} A nationwide English study of clinician-recorded PA diagnosis found that while incidence remained stable, the prevalence of PA 8 doubled, from 2001 (0.24 per 1000 patients) to 2005 (0.51 per 1000 patients).³⁸ More recently, a 9 10 three-decade, retrospective UK medical records database study found that point prevalence per 11 100,000 had risen from 31 to 202 in the total population, and from 116 to 635 in children from 2000 to 2015.⁴⁴ In addition, this study found that incidence of PA overall in the UK had more than doubled, 12 13 from 8.6 to 18.2 per 100, 000, between 2000 and 2015. However, stable PA prevalence has been reported in two Canadian studies for the periods of 2000 to 2007 in Montreal⁴⁵ and 2010 to 2017 14 across Canada⁴⁶ and in a study conducted on the Isle of Wight, UK between the late 1990s and 15 2004.47 16

17

4

18 HEALTHCARE BURDEN

19 Risks of Accidental Exposure, Severe Reactions, and Anaphylaxis

20

Even with adherence to standard self-management behaviors,^{14,16} risk of accidental exposure to peanut is still high among individuals with PA. The widespread use of peanuts in various foods makes it particularly difficult to avoid peanut exposure in the home, where children play, or at school.⁷ Data on the rate of accidental reactions in patients with PA have varied, likely due to variations in study design, geographic region, and decade of study (Table 2).^{6,20,41,48-53}

26

27 Data on the frequency of anaphylaxis in patients with PA are limited, in part because of varying

28 definitions of anaphylaxis used. Multiple studies in Western nations have reported that severe allergic

1 reactions due to peanut occur more frequently than to other food allergies.^{40,54} A nationwide US study 2 on food allergies in children (n=38,408) found that a history of severe reactions was more common in 3 children with PA (59.2%) versus all other food allergies (42.3% rate of severe reactions overall).⁴⁰ 4 Similarly, a nationwide 2009-2010 US survey study in 38,480 children found that a significantly 5 higher percentage of children with PA (n=754) had experienced a severe reaction to peanut versus 6 children with food allergy in general (n=2464) (53.7% vs. 41.0%; P<0.001).⁷ Among US adults with 7 PA, 68% report at least one severe peanut-allergic reaction versus a 51% overall rate of any severe food-allergic reactions among all US adults with food allergy.⁴¹ The Australian SchoolNuts Study, 8 9 which included 547 adolescents aged 10 to 14 years with possible food allergy, found that 38.6% of 10 all confirmed anaphylaxis episodes and 30.6% of unconfirmed anaphylaxis episodes were reactions to peanut, the highest percentages of any food causes.⁵⁵ 11

13 Studies in the US and Canada have reported that 11% to 17% of accidental exposures were severe (Table 2).^{20,50,51} A cross-sectional nationwide US study in 754 children with PA reported an 14 anaphylaxis rate of 14.2%, compared with 8.1% in children with other food allergies⁷, and a UK 15 16 clinical practice database study found a considerably lower anaphylaxis rate of 1.2% of all patients (children and children) with PA versus 0.007% of matched controls.⁴⁴ Another US study reported that 17 anaphylaxis occurred in approximately 35% of 525 children over a 5-year period,⁶ and a smaller study 18 19 (n=83) reported a 5-year rate of reactions with "potentially life-threatening symptoms" in 20 approximately 52% of children (Table 2).⁵³ Accidental exposures causing anaphylaxis frequently occur in children whose initial reactions leading to diagnosis were mild (Figure 1),^{6,53} demonstrating 21 22 the unpredictable nature of PA reaction severity.⁵⁶ While varying methodologies of reporting reactions and varying definitions of anaphylaxis make it difficult to put a finite number on the 23 24 frequency of anaphylaxis to peanut, it is evident that severe and accidental reactions are common in patients with PA. Several studies also relied on self-report, which is prone to recall bias and 25 26 misclassification. More studies are needed that examine current, consistent, and well-validated criteria 27 for the diagnosis of anaphylaxis.

28

12

Healthcare Utilisation

In the European Anaphylaxis Registry, peanut is the most common trigger involved in anaphylaxis 3 4 cases in both children and adults, accounting for 27.2% and 18.0% of food-related anaphylaxis cases, respectively.^{54,33} Peanut is also the most common food trigger involved in most studies of paediatric 5 emergency department (ED) admissions overall and in paediatric intensive care unit (ICU) admissions 6 in North America; peanut is the second most common trigger, after milk, in France.^{57,58} Anaphylaxis 7 8 to peanut is also associated with high rates of hospital admission following ED visits, compared with 9 other food-related and non-food-related causes of anaphylaxis.⁵⁹ Recent US survey data show that 10 23% of children⁴⁰ and 20% of adults⁴¹ with PA reported an ED visit in the past year due to a food-11 allergic reaction. A healthcare utilisation study in the UK demonstrated that compared to matched 12 control groups (normal and with/without an atopic condition) patients with PA had a greater number 13 of contacts (per person-year) with primary care providers, inpatient care, prescriptions, outpatient care, and accident and emergency admissions.⁶⁰ 14

15

1

16 An epidemiological study in the US, Canada, and Mexico of paediatric anaphylaxis ICU admissions between 2010 and 2015 (n=1989) found that peanut was the most frequent trigger, accounting for 17 39% of such cases (Figure 2).⁵⁷ In addition, a study of paediatric ED visits and hospital admissions 18 19 due to food-induced anaphylaxis in Illinois between 2008 and 2012 found that such cases had 20 increased significantly over the period (P < 0.005), with a 30% average annual increase observed for peanut-induced events (Figure 3).⁶¹ A nationwide Italian study found that the rate of hospital 21 22 admissions for food-induced anaphylaxis in children had increased from 0.001% in 2001 to 0.005% in 23 2011 (P < 0.05), and that while peanut exposure was a less frequent cause than milk and eggs, it was 24 the cause of 1 out of every 4 deaths that occurred in patients aged >14 years.⁶²

25

Although sparse, these utilisation data support and confirm the studies discussed in the previous
 section showing relatively high rates of anaphylaxis and severe reactions despite their diversity of
 methodology.

Economic Burden

1 2

3

4

5

The economic burden of PA includes both direct and indirect costs, each of which have been investigated in several studies.

6 Direct medical costs

Among US studies, a retrospective national US government healthcare database analysis of the annual direct costs of food allergy, including PA, over the years 2006 and 2007 estimated that total annual 8 9 medical costs were \$225 million (2007 US dollars), with office visits accounting for just over half of 10 the cost; the rest of the cost was split among ED visits, inpatient and outpatient visits, ambulance transfers, and AAIs.⁶³ A survey of US caregivers of children with food allergy estimated direct 11 medical costs of \$4.3 billion annually (or \$724 per child).⁶⁴ The caregivers also reported a willingness 12 to pay \$3504 per year per child for a safe and effective treatment that would allow the child to eat all 13 14 foods; that total cost was estimated at \$20.8 billion annually, a number similar to the total estimated 15 indirect costs spent on children with food allergy (\$20.5 billion). The total annual economic burden of 16 food allergy was estimated to be \$24.8 billion, which combined direct (\$4.3 billion) and indirect costs.⁶⁴ A 2013 pan-European, case-control survey study conducted among participants in the 17 EuroPrevall study (n=1411) found that the mean costs of health care over the previous year for adults 18 19 and children with possible food allergy (symptoms unconfirmed by psIgE testing) were I\$2016 and 20 I\$2197 versus I\$1089 and I\$863 for controls, respectively.⁶⁵

21

22 Among studies that assessed the costs of PA specifically, a 2017 white paper found that patients with 23 PA averaged approximately 1.25 medical services per patient in 2016 based on an analysis of 24 nationwide US medical insurance claims.⁶⁶ On average, patients with PA were charged \$236.73 per patient for services over the 2016 year, with insurance covering \$100.11. A US study assessed value-25 26 based pricing for an AAI, which is substantially higher in the US than most other countries, for 27 community-based anaphylaxis management in patients with PA.²¹ This study found that given the 28 average pharmacy AAI cost of \$715 in 2016, combined with 2018 reported costs for ED visits and 29 hospitalisations for anaphylaxis symptoms, the cost of anaphylaxis preparedness and treatment in

1 those prescribed an AAI over an 80-year time horizon was \$25,478 (95% CI: \$25,399-\$25,447) 2 versus \$654 (95% CI: \$685-\$743) for those not prescribed an AAI. Assuming that AAI prescription 3 reduced anaphylaxis fatality risk by 10- to 100-fold, the estimated cost-effective price range for AAI 4 was \$24 to \$264, indicating that AAI at its then-current US price was not cost-effective. A 5 retrospective cohort study of PA costs among patients with PA in the UK (n=15,483), reported per-6 person annual incremental healthcare costs versus healthy controls of £333, ranging up to £392 for 7 those prescribed an AAI, and £662 per year for those with history of anaphylaxis; total excess costs of PA in the UK were between £33 and £44 million in 2015.⁶⁰ The average cost of an AAI in the UK in 8 2017 was £25.80 (approximately US\$32.10).⁶⁷ Comparable studies of PA costs in regions/countries 9 10 other than the US and UK are lacking. The available studies rely on modelling and reflect vastly 11 disparate healthcare costs in different countries; thus, defining the exact costs of PA across countries 12 remains difficult. However, the consistent finding among these studies is that PA raises healthcare 13 costs.

14

27

15 Indirect medical costs

16 A Swedish case-control study demonstrated that indirect costs of food allergy were significantly 17 higher in families with food-allergic children (excluding adolescents) compared with controls.⁶⁸ The 18 US retrospective, government healthcare database study mentioned above also estimated annual 19 indirect costs (e.g. lost work productivity and earnings) of food allergy including PA for 2006-2007 to be \$115 million (2007 US dollars).⁶³ A cross-sectional US survey study⁶⁴ estimated annual lost labor 20 21 productivity due to food allergy at \$773 million, or \$130 per child, associated with accompanying 22 child to medical visits; \$5.5 billion, or \$931 per child, in annual out-of-pocket costs, including special 23 diets/allergen-free foods, changes in childcare, and changes in schools; and annual opportunity costs 24 due to forgone labor market activities, at \$14 billion, or \$2399 per child. While these studies have 25 limitations, similar to those analysing direct costs, an overall trend towards increased indirect costs is 26 apparent.

Mortality

1 2

While rates of fatal anaphylaxis due to peanut are low, peanut is among the most frequent food 3 allergens implicated in fatal anaphylaxis. This finding has been documented in the US,⁶⁹⁻⁷¹ the 4 UK,^{72,73} Australia,⁷⁴ and France.⁷⁵ A 2013 meta-analysis of data on fatal food-related anaphylaxis 5 found that the incidence of peanut-induced mortalities was 2.13 per million person-years (95% CI: 6 1.09, 4.16; I-squared=86.4%; P < 0.001), which was higher than the rate for all food allergies (1.81 per 7 million person-years [95% CI: 0.94, 3.45; I-squared=94.8%; P<0.001]).⁷⁶ UK data showed that 8 9 deaths from food-related anaphylaxis usually occurred in allergic people whose previous reactions 10 had been mild, underlining the unpredictability of reaction severity, although presence of asthma and asthma exacerbation were identified as mortality risk factors.⁷³ A 2018 meta-analysis of 32 published 11 12 studies of food-related anaphylaxis, which found that peanut and tree nuts were the leading triggers of 13 fatal anaphylaxis, also showed that a history of asthma in young adults was an important risk factor 14 for fatality.77

15

16 Comorbidities

17

Comorbid conditions including allergic rhinitis, atopic dermatitis, and asthma, as well as other food allergies are very common in patients with PA (Table 3)^{4,6}; in the French MIRABEL study, only 5% of individuals had no associated allergic comorbidity.⁴ Comorbid tree nut allergy is particularly common in patients with PA, with reported prevalence ranging from approximately 16% to 50%.^{7,78} In tree nut–allergic patients, reported concomitant PA ranges from 20% to 68%.⁷⁹ Increased number of food allergies tends to increase the burden due to the added requirements of vigilance and dietary restriction.⁸⁰

25 THE BURDEN OF PEANUT ALLERGY ON THE INDIVIDUAL

26

Dietary Restrictions

The primary strategies for allergen avoidance in patients with PA and their families are diet 3 4 modification and restrictive eating habits, which has a substantial impact on quality of life (QoL).¹⁸ 5 These strategies also carry the risks of nutritional deficiency and compromised growth in young children, particularly if parents exclude a wider-than-necessary range of foods without expert 6 nutritional consultation.⁸¹⁻⁸³ Individuals with PA often avoid tree nuts, in part because of concern over 7 cross-reactivity or contamination.⁴⁹ However, studies that investigated rates of coexistence of nut 8 9 allergies have shown that performance of SPT or basophil activation tests or OFCs for various nuts in 10 children with one or more PA or other nut allergies could result in relief of dietary restrictions.^{84,85} In 11 the PRONUTS study, use of OFC to confirm tolerance of specific nuts in children with ≥ 1 nut allergy 12 led to a median of 9 nuts being introduced into the diets of study participants.⁸⁵

- 14 Reading Food Labels: Precautionary Allergen Labels
- 15

13

1

16 Mandatory requirements for allergen labelling in food items are well established in developed and 17 developing countries and are typically clear and useful.⁸⁶ However, *precautionary* allergen labelling is not legally required in most countries, is mostly unregulated, and may be confusing for consumers.⁸⁶ 18 19 In a US study of prepackaged food labelling just under half of products included had a "may contain" 20 type of advisory label.⁸⁷ A 2017 study from France found that of more than 17,000 food products, 1% 21 included peanut in the ingredient list, yet 13% of products contained a precautionary statement listing peanut.⁸⁸ In addition, an investigation by the Food Standards Agency in the UK found that 22 23 approximately 20% of food samples in England contained an undeclared allergen, the majority of which were peanuts.⁸⁹ In a longitudinal, prospective cohort study in the Netherlands, among 157 24 25 patients with food allergy, including 71% with PA, 73 reported 151 accidental reactions to an allergen, of which 118 (78%) could be attributed to a specific product.⁹⁰ Of the 51 food products that 26 27 fulfilled criteria for further analysis, 19 (37%) contained 1 to 4 allergens (including peanut) that were 28 unidentified in the product labelling.

2 Several studies have shown that using unregulated language in advisory statements on food labels may create uncertainty for consumers. A US-based study showed that only 4.5% of products with 3 advisory labelling specific to peanuts tested positive for peanut residue, further unnecessarily 4 restricting diet choices.⁹¹ In addition, shoppers increasingly ignore labels,⁹² with up to 40% of US and 5 6 Canadian consumers who either have a food allergy or care for a food-allergic child stating they had purchased food despite the product's precautionary labelling, in one study (Supplemental Table 2).93 7 8 The French MIRABEL study found that accidental exposure peanut doses eliciting reactions were 9 <100 mg in 44.3% of study participants with PA; however, such data have not been incorporated into 10 clear and universal labelling regulations.⁴ The quantity of accidentally ingested peanut leading to 11 symptoms in patients with PA appears to vary widely and is not well studied.

12

1

The lack of consensus for standard labelling impairs the ability of healthcare professionals to provide an effective management approach, and may indirectly impact emotional adjustment, social interactions, and coping strategies,⁹⁴⁻⁹⁷ causing increased anxiety and impaired QoL.⁹⁸ Recent recommendations from The National Academies of Sciences, Engineering, and Medicine (NASEM) highlighted the importance of evaluating and improving food labels with allergen information.⁹⁹

18

19 Eating at Restaurants

20

21 Eating food made outside of the home can also impact patients with PA, as peanut is a common 22 ingredient in many dishes. The 2017 NASEM consensus report recommended that patients and their 23 parents be guided to always inform restaurants (e.g. servers, managers, cooks) of food allergies to 24 minimise risk of exposure.⁹⁹ The European Commission of the European Union also issued legislation 25 effective December 2014 including "mandatory allergen information for non-prepacked food, including in restaurants and cafes."¹⁰⁰ In 2019, the European Federation of Allergy and Airways 26 27 Diseases Patients' Associations released a report calling for additional improvements to food labelling and safety measures at restaurants.¹⁰¹ 28

A survey of children with peanut- and tree nut allergy who experienced a reaction due to exposure at a 2 restaurant (dine-in or takeout) found that most reactions (81%) were due to accidental exposure in 3 4 children who had already been diagnosed; yet allergic individuals or their parents alerted restaurant 5 personnel about the allergy less than half (45%) of the time.¹⁰² Surveys of restaurant workers in the US, UK, Turkey, and Malaysia, have demonstrated a poor understanding of food allergies and 6 appropriate measures for avoiding allergens.¹⁰³⁻¹⁰⁹ A UK interview study found that individuals with 7 food allergy strongly preferred written information to be provided in restaurants.¹¹⁰ Respondents 8 9 further reported they practiced avoidance as a last resort if uncertain.

10

1

11 **Restrictions on Daily Activities**

12

13 The risk of accidental exposure posed by PA extensively impacts daily activities, which may include 14 playdates at friends' homes, attendance at daycare or afterschool care, parties and sports events, and 15 camp and sleepovers.¹¹¹

16

17 Travel

18

Individuals with PA must take extra precautions in trip planning. A survey of this population in the
 UK highlighted several such considerations, including ability to understand the language at the
 destination, perceived experience on airlines, accessibility to medical care, familiarity with the
 destination, and avoiding unfamiliar cuisines.¹¹²

23

An international study of 3273 respondents with peanut and/or tree nut allergy from 11 countries found that 349 reactions to peanuts or tree nuts occurred aboard flights, with 13.3% of respondents

26 receiving adrenaline for their reactions.¹¹³ In addition, flight crews were notified of the reactions in

only 50.1% of cases. However, 69% of respondents made preflight accommodation requests (55% of
 reactors vs. 71.6% of nonreactors; *P*<0.001).

School

5

19

27

6 European meta-analysis data indicate that food allergy affects 4%-7% of primary school children, and 7 approximately 8-20% of paediatric food-related accidental reactions and anaphylaxis reactions may 8 occur at school.¹¹⁴ Peanut was the most common trigger among 105 cases of food-induced anaphylaxis (25% of cases) at school documented in a French national allergy database,¹¹⁵ and was 9 10 the second most common food trigger of anaphylaxis (16%), after tree nuts (23%), occurring in school settings in one German study (n=87 anaphylaxis cases).¹¹⁶ ¹¹⁵A US study of all food-allergic 11 12 reactions due to accidental exposure at school found that 25% to 29% of reactions were attributed to peanut.¹¹⁷ In a survey study of parents of children with PA or tree nut allergy in the US Peanut and 13 14 Tree Nut Registry (n=4586), 16% of respondents reported a reaction at daycare, preschool, or elementary school.¹¹⁸ Of the 124 total reactions (115 to peanut), 65 (52.4%) were severe and 71 15 16 (57.3%) were treated with adrenaline. A further study in this registry population (n=5149) also found 17 that as children got older, school was increasingly the setting for accidental exposures subsequent to 18 the child's first reaction (Figure 4).48

Multiple studies in various countries have examined potential strategies for schools to address the risks of food allergies, such as becoming "peanut-free" and making adrenaline available to school staff, with some controversy.^{115,116,119-127} A survey of school nurses in Massachusetts found that 10.3% of schools do not permit peanuts to be sent in from home, 91.1% had peanut-free tables, and 65.6% had peanut-free classrooms.¹²⁸ However, a study investigating the impact of peanut-free schools on the PA-related burden and QoL of parents demonstrated no difference compared with schools that are not peanut-free.¹²⁹

Emotional Impact

Living with food allergy can lead to fear and anxiety not only regarding the risk of exposure and 3 reaction to the allergen,¹¹¹ but also fear of using a prescribed AAI, possibly related to uncertainty of 4 how and when to use it and past or anticipated traumatic experiences of severe reactions ^{19,130-132} In 5 those with PA, factors such as comorbid illnesses and experience of PA may also play a role. The 6 MIRABEL study in 785 children with PA found that higher anxiety scores (n= 401 evaluated for 7 8 anxiety) were observed in patients with atopic dermatitis (P=0.003), both atopic dermatitis and 9 asthma (P=0.032), and those who had received strict avoidance advice (P<0.001).⁴ Dietary avoidance 10 itself may also be a source of anxiety and stress.^{18,133}

11

1

12 Bullying, teasing, and taunting because of food allergy have been reported among children with food allergy in studies at rates ranging from 16% to 71%, causing substantial adverse emotional impact.¹³⁴ 13 14 Data specifically on bullying in children and adolescents with PA is scant. One survey study of children and adults with food allergy included 287 individuals with PA.135 In this study, 24.1% 15 16 reported having been bullied, harassed, or teased because of their food allergy by a variety of 17 perpetrators (Figure 5A). After excluding children younger than 5 years, the rate increased to 35.2%. 18 The great majority of those bullied, teased, or harassed (85.9%) reported physical acts of bullying 19 such as having the allergen waved in their face (Figure 5B); nonphysical acts included verbal teasing 20 and exclusion. The most common reported emotional effects of the bullying were sadness and 21 depression, embarrassment and humiliation, and nervousness and anxiety (Figure 5C). 22

23 Impact on Health-Related Quality of Life/Quality of Life

24

Multiple studies have demonstrated adverse impacts of food allergy on HRQoL and QoL in people with food allergies and their parents/caregivers.^{132,136,137} Several studies also evaluated the effects of PA specifically on HRQoL, which is of particular interest since PA is associated with relatively high rates of prevalence, accidental exposures, severe reactions and anaphylaxis, as discussed above.^{17-19,80}

2 A recent study surveyed parents of children aged <13 years with PA (n=717), sesame allergy (n=34), 3 or seafood allergy (n=42) using the Food Allergy Quality of Life Questionnaire—Parent Form.⁸⁰ Mean OoL scores (higher scores=worse QoL) were similar for PA (2.53) and sesame allergy (2.56), 4 5 but scores were significantly worse for PA (but not sesame allergy) compared to seafood allergy 6 (1.97; 0.55 difference, 95% CI: 0.13, 0.98). An older study compared QoL of children with PA (n=20; mean age 9.0 years) and diabetes mellitus (n=20; mean age 10.4 years) using a QoL questionnaire developed for the study (which has since been validated)¹³⁸ and an adapted Vespid Allergy Quality of 8 Life questionnaire.¹⁷ In this study, mean scores were significantly higher (worse) in children with PA 9 10 versus those with diabetes in both questionnaires (54.9 for PA vs 46.4 for diabetes; P=0.004 [novel 11 questionnaire] and 54.3 for PA vs 34.5 for diabetes; $P \leq 0.001$ [adapted Vespid questionnaire]) (Figure 12 6). The children with PA were also reported to experience significant anxiety in a wide range of 13 settings.17

14

1

15 A study in 46 families that included a child with clinically confirmed PA, and which used validated 16 QoL and anxiety and stress scales, reported significantly worse scores for physical HRQoL (P < 0.05), QoL within school (P < 0.01), general QoL (P < 0.05), and greater separation anxiety (P < 0.05) in 17 children with PA than in their siblings without PA.¹⁸ Mothers had significantly worse scores for 18 19 psychological and physical health, and higher levels of anxiety and stress than fathers. However, 20 another study, which examined HRQoL, anxiety, and stress levels in 51 families including a child 21 with PA, found that many measures did not significantly differ from population norms.¹⁹ This study 22 also found that parental stress and child anxiety levels varied with clinical history, and that both 23 parent and child perceptions of their own HRQoL were affected by each other's anxiety and stress 24 levels. Children's QoL was also adversely affected by length of time since diagnosis and the experience of having to self-inject or receive an AAI injection. 25

26

Depending on the management strategies employed by children with PA and their families, the impact
 of PA on QoL is variable.¹³⁹ Further, management of PA by paediatric allergy specialists has been

shown to slightly improve QoL,¹⁴⁰ demonstrating a crucial role for allergists and immunologists in
 helping allergic children and their families manage this burden.

CONCLUSIONS

3

4

20

The incidence and prevalence of PA appear to be increasing, and rates of accidental exposure in patients with PA are high, despite extensive efforts at avoidance. Patients with PA and their families 8 experience significant psychosocial and economic ramifications from PA allergy, resulting in a 9 negative impact on HRQoL/QoL. Multiple new approaches and initiatives towards better 10 understanding of PA risks and improved PA management are clearly needed (Table 4). Introduction of peanut to children at a young age may reduce the risk of developing PA,²³ and international 11 guidelines for the use of this approach have been provided.²⁴⁻²⁶ However, such prevention practices do 12 13 not address those with PA or who develop PA despite this new guidance. While the approval of the first oral immunotherapy product for PA²⁷ is a major advance, the ultimate benefit of this therapy and 14 other new treatments will likely depend on multiple factors including baseline disease severity, the 15 16 cost-effectiveness of immunotherapies versus adrenaline, effects of immunotherapy on QoL, and the 17 ability to induce sustained unresponsiveness.¹⁵ Continued research into the burden of PA remains 18 essential to provide perspectives for current and future developments in PA management. 19

Other	40.8	NR	NR	NR	NR	NR	

EoE, eosinophilic oesophagitis; NR, not reported.

Table 4. The State of Knowledge on the Burden of Peanut Allergy and Future Needs: An Overall Assessment

Area of Assessment	Current Knowledge and Needs
What is known	• PA affects 1% to 2% of the general population, and appears to be increasing in
	prevalence and incidence, in Western nations
	• PA is typically lifelong and is associated with high rates of severe reactions and
	anaphylaxis due to accidental exposures, compared with other food allergies
	• Peanut is among the most frequent allergens implicated in documented cases of
	fatal food-related anaphylactic reactions
	• PA is associated with high rates of healthcare utilisation and costs
	• The risks of PA impose restrictions in multiple activities of daily living for
	patients, parents, and caregivers, including food shopping, dining out, socializing schooling, and travel
	• Management of PA risks in consumer food labelling, and accommodations at
	schools, restaurants, and travel are inconsistent and often inadequate
	• Bullying of children with PA is common, causing emotional impacts including
	sadness, humiliation, and social isolation
	• QOL is significantly reduced for patients with PA, parents, and caregivers,
	possibly more so than in other chronic diseases
What is likely	• The incidence of PA may increase in regions other than Western/advanced
	nations as they adopt Western styles of diet and pediatric nutrition management
	• Costs of future PA treatments may meet with acceptance if they approximate the current costs of AAIs
	• Recent guidelines for prevention of PA in infants may stabilise or decrease PA
	prevalence and incidence
What is needed	• Improved and more consistent methodology for study of PA epidemiology
	• More and better data on PA epidemiology from geographic regions other than
	Western/advanced countries
	• More and better data on the healthcare utilisation and costs of PA from
	regions/countries other than the US and UK

• Standardized, clear, and evidence-based food-labelling for peanut content
• Increased knowledge/studies on the amount of peanut in foods that will cause
reactions, and the circumstances of/risk factors for accidental reactions (e.g.
where they occur)
• Improved and more consistent standards for accommodations for individuals with
PA at public establishments such as restaurants, schools, and travel conveyances
• More accurate QOL instruments adapted specifically for PA including those that
may measure the impacts of treatment of PA on QOL
• Treatments that reduce the risk of severe reactions due to accidental exposure to
peanut and may alleviate the burden of PA
• Further studies to assess peanut OIT efficacy and safety, establish validated
protocols for optimal dosing and duration of therapy, and assess impact on QOL
and cost effectiveness.

PA, peanut allergy; OIT, oral immunotherapy; QOL, quality of life.

Accebté

FIGURE LEGENDS

Figure 1. History and nature of reactions to peanut from a single-centre study in 83 children with peanut allergy followed for 5 years. Approximately one-third of subjects who had non-life-threatening first reactions (19 of 61; 31.1%), and more than half of those who had life-threatening first reactions (12 of 22; 54.5%), subsequently experienced a/another potentially life-threatening reaction. All reactions subsequent to first reaction were from accidental exposure (as opposed to reactions occurring during food challenges).⁵³

Figure 3. From an Illinois (United States) state hospital association database study of emergency department (ED) visits or hospitalisations for food-induced anaphylaxis in Illinois hospitals from 2008 to 2012 (n=1893; 10.9 ED visits or hospitalisations per 100,000 children). A. Rates of ED visits and hospital admissions due to food-induced anaphylaxis by food allergen trigger. B. Annual percent increase in ED visits from 2008 to 2012. Asterisk indicates a statistically significant increase from 2008 to 2012 (P < 0.005).⁶¹

Figure 4. Settings of first and subsequent reactions among 5149 registrants in a peanut and tree-nut allergy registry, of whom 89% were children (aged <18 years), 68% had isolated peanut allergy, and 23% had both peanut and tree-nut allergy. Accidental exposures to peanut subsequent to the first reaction occurred increasingly at school settings. "Other" locations include workplace, stores, malls, sporting event sites, transportation vehicles, and houses of worship .⁴⁸ Reproduced with permission from Sicherer SH, Furlong TJ, Munoz-Furlong A, Burks AW, Sampson

HA. A voluntary registry for peanut and tree nut allergy: characteristics of the first 5149 registrants.2001;108(1):128-132.

Figure 5. Bullying: respondents who reported having been bullied because of their/their child's food allergy (n=85) from a survey study in 353 individuals with food allergy, including 287 (81.3%) with peanut allergy. Panel A describes the perpetrators of the bullying. Panel B describes the types of physical bullying. Panel C shows the reported emotional effects of bullying. For each parameter, respondents could select more than one perpetrator, type of bullying, and emotional effect.¹³⁵ Reproduced with permission from Lieberman JA, Weiss C, Furlong TJ, Sicherer M, Sicherer SH. Bullying among pediatric patients with food allergy. *Ann Allergy Asthma Immunol.* 2010;105(4):282-286.

Figure 6. Scores on specific questionnaire items in study comparing quality of life in children with peanut allergy (blue bars; n=20) and diabetes mellitus (orange bars; n=20). A. Fear of eating peanuts/having a hypoglycemic event; B. Chance of having a bad reaction and getting very sick; C. I have to be very careful about what I eat; D. I must take care when eating in a restaurant.¹⁷
